The Tropospheric Land-Sea Warming Contrast as the Driver of Tropical Sea Level Pressure Changes

Journal of Climate, accepted, 26.08.2012

Abstract

In this article we address the causes of the large-scale tropical sea level pressure (SLP) changes during climate change. The analysis we present is based on model simulations, observed trends and the seasonal cycle. In all three cases the regional changes of tropospheric temperature ($T_{tropos}$) and SLP are strongly related to each other (considerably stronger than (sea) surface temperature and SLP). This relationship basically follows the Bjerknes Circulation Theorem, with relatively low regional SLP where we have relatively high $T_{tropos}$ and vice versa. A simple physical model suggests a tropical SLP response to horizontally inhomogeneous warming in the tropical $T_{tropos}$, with a sensitivity coefficient of about -1.7 hPa/K. This relationship explains a large fraction of observed and predicted changes in the tropical SLP.

It is shown that in climate change model simulations the tropospheric land-sea warming contrast is the most significant structure in the regional $T_{tropos}$ changes relative to the tropical mean changes. Since the land-sea warming contrast exists in the absent of any atmospheric circulation changes it can be argued that the large-scale response of tropical SLP changes is to first order a response to the tropical land-sea warming contrast. Further, as land-sea warming contrast is mostly available moisture dependent, the models predict a stronger warming and decreasing SLP in the drier regions from South America to Africa and a weaker warming and increasing SLP over the wetter Indo-Pacific warm pool region. This suggests an increase in the potential for deep convection conditions over the Atlantic Sector and a decrease over the Indo-Pacific warm pool region in the future.
1. Introduction

The Fourth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) predicts a substantial global warming with a well-defined 3-dimensional spatial pattern in atmospheric temperatures for future anthropogenic climate change. How the tropical sea level pressure (SLP) and atmospheric circulation changes in response to these atmospheric temperature changes is the focus of this study.

The atmospheric temperature response to increasing greenhouse gas concentrations in the tropics has two important large-scale features: a vertical increase in warming of the troposphere and a land-sea warming contrast. The vertical increase in warming in the tropical troposphere is associated with the enhanced hydrological cycle (Held 1993; Held and Soden 2006) and is accompanied by a weakening of the large-scale tropical circulation (Vecchi et al. 2006; Vecchi and Soden 2007; Vecchi et al. 2008). The second feature, which is not restricted to the tropical regions, is the marked land-sea contrast of surface and low-level warming, i.e. a (stronger) heating over land relative to the oceans. This is not just a transient effect caused by difference heat capacities of land and oceans, but is due to differences in feedbacks related to the available moisture (Sutton et al. 2007; Joshi et al. 2008; Dommengen 2009).

How land-sea contrast is generated is illustrated in Joshi et al. (2008): Above a certain level in the middle troposphere the warming is more or less horizontal uniform due to a strong mixing of these air masses (see also Fig. 1a upper levels). Below this level, local feedbacks dominate the lapse rate and the warming. Due to more available latent heat the lapse rate is lower where the moisture content is higher and vice versa, with the dry adiabatic lapse rate as upper boundary. Thus starting at the same temperature in the middle troposphere and following a moisture dependent adiabat we yield a higher surface temperature at drier air columns and lower surface temperature at wetter air columns. Available moisture is limited over land, so that we get in general a stronger warming over land than over ocean, thus a land-sea warming contrast. Thus the terminology “land-sea contrast” can be a little bit misleading, because it is mostly an “available moisture contrast”.

Important aspects of land-sea warming contrast are shown in Figure 1a: In the vertical it is most pronounced near the surface and in the horizontal it is strongest over the arid subtropical land masses. In the layer from 850 to 500 hPa the dry trade wind inversions over the East Atlantic and East Pacific warm nearly as strong as the dry air over the subtropical land masses. The humid Maritime Continent has only a weak land-sea contrast at surface and no land-sea contrast in the lower troposphere. These two features become clearer in Figure 1b: The Maritime Continent cools above the lowest levels more ocean-like and the Atlantic warms above the lowest levels more land-like.

The upper boundary of the land-sea warming contrast varies over the individual oceans and continent (in agreement with Joshi et al. 2008), while in the tropical wide perspective it is at the 400 hPa level (Fig. 1b). In summary it is quite obvious in this figure that horizontal differences in the warming of each tropospheric level relative to the level’s mean warming are highest in the lower levels, which are strongest affected by the land-sea warming contrast. Since horizontal temperature gradients are one of the main drivers of the longitudinal atmospheric circulation cells, it seems plausible that the land-sea warming contrast could be an important driver of tropical circulation and SLP changes, like in Bala et al. (2011), where they show that an artificial land-sea warming contrast due to geoenginerieing enhances the uplift and decreases the SLP over tropical land masses.

In general there is an important contrary relationship between temperature and SLP. This can be observed in monsoon circulation and land-sea breeze and is described
by the Bjerknes Circulation Theorem: Heating at one place and cooling at the other will
induce a nearly direct circulation, with rising air and low SLP at the heat source and
sinking air and high SLP at the heat sink (e.g. Bjerknes et al. 1898; Gill 1980; Thorpe et
al. 2003), assuming that in the tropics the Coriolis force can be neglected. On regional
scales previous studies (e.g. Hu et al. 2000) found that this relationship can explain the
intensification of the Asian monsoonal circulation by the land-sea warming contrast.

We can now do a first simple thought experiment: We know that there are the
three relatively warm places in the tropics (Indo-Pacific warm pool region, South Ameri-
can and Africa), where the main deep convection takes place and SLP is low (Krueger and
Winston 1974). We also know, that in climate change projections due to land-sea warming
contrast two of the three warm places (Africa and South America) warm stronger
than the third one (Indo-Pacific warm pool region, see Fig. 1), because highly available
moisture reduces the warming there. Having the Bjerknes Circulation Theorem in mind
we would expect from this little thought experiment that on large scale the SLP will in-
crease over the warm pool region and decrease over Africa and South America, if land-
sea warming contrast is the dominant feature in the SLP trends.

In recent years the tropical SLP response in a warmer climate was often dis-
cussed in the context of the weakening of the tropical circulations over the Pacific re-
gion, thus also on a more regional than global scale. Since the land-sea warming contrast
acts on a global scale the question arises, if the large scale SLP response in the tropics
can be explained with the land-sea warming contrast?

To describe this relationship between temperature and SLP as precisely as possi-
ble the temperature information of the atmosphere and not only of the surface is im-
portant, as indicated by the integration along the circulation path in the Bjerknes Circu-
lation Theorem and stated in Flohn (1975). Further, considering only changes in surface
temperature neglects the potentially important effect of the land-sea warming contrast
in the lower troposphere. As we will see in the results section the SLP response in a
warmer climate can be described considerably better if the temperature change over the
full tropospheric circulation domain is considered, thus from surface to tropopause.

The focus of this study is to investigate the link between tropospheric tempera-
ture ($T_{tropos}$) and SLP changes in climate model simulations of future climate change sim-
ulations and in observations. We aim to present a simple physical model that can explain
a large fraction of the large-scale response of the tropical SLP in a warming climate. The
paper is organised as follows: Section 2 gives an overview of the data used in this study.
This is followed by the first analysis in Section 3, in which we investigate the relation
between $T_{tropos}$ and SLP in the mean seasonal cycle to establish the link between $T_{tropos}$
and SLP. In Section 4 a simple physical model for the tropical SLP response is introduced
that quantifies the linear relation between $T_{tropos}$ and SLP. The $T_{tropos}$ and SLP trends of a
climate change multi model ensemble are examined in Section 5 and 6. The model simu-
lation analysis is complemented by an idealised land-sea contrast experiment in Section
7 and the trends in observations are investigated in Section 8. We conclude our analysis
with a summary and discussion in Section 9.

2. Data

Observed atmospheric temperatures and SLP are taken from the ERA Interim re-
analysis (Simmons et al. 2007) for the available period from 1989 to 2010. Over this pe-
riod, the tropical temperature trends are in good agreement with satellite observations
(Bengtsson and Hodges 2009). We assume that the reanalysis products are the best es-
timates of observed tropospheric temperatures for this study, in particular due to the
lack of sufficient coverage of ‘real’ observations for the vertical air temperature profile.
The future climate change simulation data used are from 23 coupled model simulations of the Climate Model Intercomparison Project 3 (CMIP3) data base (Meehl et al. 2007b). We took all simulations from the CMIP3 data base which have atmospheric temperature and SLP for the IPCC 20C and A1B scenario available, interpolated all data on a regular 2.5° x 2.5° grid and calculated a multi-model ensemble mean with one ensemble member from each model. Missing atmospheric temperature values due to topography are interpolated from the levels above, following a moist adiabatic temperature profile.

Additionally we analyzed a set of sensitivity experiments with the ECHAM5 atmospheric general circulation model (Roeckner et al. 2003) in T31 horizontal resolution (3.75° x 3.75°) coupled to a single column mixed layer ocean, as described in Dommengen (2009). We analyzed two 50 yrs long sensitivity experiments in which the land surface temperatures with +1K and -1K differences from a reference climatology are prescribed; see Dommengen (2009) for details.

For all following analysis we defined the tropospheric temperature, \( T_{\text{tropos}} \), as the vertical average of mass weighted air temperature from 1000hPa to 100hPa, i.e. approximately the entire troposphere. The tropics are defined as the region from 23°N to 23°S.

3. The Seasonal Cycle of Tropical SLP and \( T_{\text{tropos}} \)

As a starting point for this study, we analyse the observed seasonal changes in tropospheric temperatures and SLP, as it provides a zero order estimate of the tropical circulation response to changes in tropospheric temperatures or to external forcing (incoming solar radiation in this case) in general. In Figure 2a-d we compare the seasonal mean \( T_{\text{tropos}} \) relative to the tropical total mean \( T_{\text{tropos}} \) with the seasonal mean SLP relative to the tropical total mean SLP. We can first of all note that the tropics have three regions of relative warm \( T_{\text{tropos}} \) over Africa, South America and the Indo-Pacific warm pool region (including Australia), which are also called the three main ‘heat sources’, where the main deep convection takes place (Krueger and Winston 1974). These warm regions are separated by the cooler eastern Pacific and Atlantic and cooler regions towards higher latitudes. Following the seasonal cycle these regions shift mostly in north-south directions.

More importantly in the context of this study we can see, that the patterns of relative \( T_{\text{tropos}} \) and SLP in all four seasons are highly anti-correlated with each other (Fig. 2a-d): The three main ‘heat sources’ in the tropics coincide with the regions of lowest SLP (Matsumo 1966), as expected from the Bjerknes Circulation Theorem. The net mass exchange with the extra-tropics from season to season is small (despite the flow from summer to winter hemisphere), so that air masses redistribute mainly within the tropical band.

Another way of illustrating the strong relationship between relative \( T_{\text{tropos}} \) and relative SLP is to regress all four seasonal mean relative \( T_{\text{tropos}} \) values against the relative SLP for all grid points, as shown in Figure 3. The distribution indicates a clear linear relationship between relative \( T_{\text{tropos}} \) and relative SLP consistent with the above discussion. As a first measure of the relation, we obtain from a linear regression a -2.4 hPa change in SLP per 1 K warming in \( T_{\text{tropos}} \) in the seasonal cycle, which can explain 76% (\( R^2 = 0.76 \)) of the SLP seasonal means with the \( T_{\text{tropos}} \) seasonal means.

4. A Simple Model for Tropical SLP Response to Changes in \( T_{\text{tropos}} \)

From simple physical considerations we can build a physical model to estimate the linear relationship between relative \( T_{\text{tropos}} \) and relative SLP in the tropics. Figure 4 illustrates how a regionally different warming of \( T_{\text{tropos}} \) can cause a mass redistribution
and therefore a change in \( SLP \). Regarding to the Bjerknes Circulation Theorem we propose the following mechanism behind the simple model: We consider initially two air columns with the same temperature and pressure (Fig. 4a). Warming the left column will expand the air, and cooling the right will contract the air (Fig. 4b). In the real world the Bjerknes Circulation tires to balance the temperature differences and induces a lateral mass flow between the warmer and the colder air column and causes a \( SLP \) change. In our physical model we assume that the heights of the two columns are balanced at the end again (Fig. 4c). As in a hydrostatic framework the pressure is just the weight of the mass above we start in our simple model with the hydrostatic equation:

\[
dp = -\rho \, g \, dh
\]  
with pressure \( p \), density \( \rho \), gravity constant \( g \) and air column height \( h \). With

\[
dh = \frac{h}{T} \, dT
\]
we can calculate the isobaric thermal expansion of the air column using ideal gas law, with temperature \( T \). To balance the heights of the two columns at the end, half of the height difference is moved from the warmer to the colder air volume. So with both equations we obtain for the \( SLP \) change in dependency of the temperature change:

\[
\frac{dp}{dT} = 0.5 \, \rho \, g \, \frac{h}{T}
\]
Our model assumes lateral mass flow so that the pressure changes of many thin air volumes integrated vertically over the whole column is the same as the mass flow of one 900 hPa thick column, so that the hydrostatic equation can be used. From ERA Interim we obtain for the mean tropospheric density \( \rho = 0.562 \, \frac{kg}{m^3} \), troposphere height \( h = 16.5 \, km \) and tropospheric temperature \( T = 263.6 \, K \) so that we yield a pressure change of \(-1.7 \, hPa\) at the surface per \( K \) warming of the tropospheric air column above. This value is close to the statistical regression coefficient found in Fig. 3, indicating that the simple model describes a significant part of the \( SLP \) response to \( T_{tropos} \). However, there is also a statistically significant deviation from the observed relationship, indicating that the model is not a complete match.

There are four assumptions for this model: First, the model only considers relative (inhomogeneous) changes in \( T_{tropos} \) and \( SLP \), which means a mass redistribution only inside the tropics for \( SLP \) and a local heating relative to the tropical average for \( T_{tropos} \). Thus the area mean is removed from \( SLP \) and \( T_{tropos} \) (as in Fig. 2a-d) before applying the simple model. A homogenous warming of \( T_{tropos} \) has no effect on \( SLP \), as they would not induce any regional \( SLP \) changes (mass redistribution inside the tropics). The seasonal changes of the absolute values of \( T_{tropos} \) and \( SLP \) (Fig. 2a-d) are an order of magnitude smaller than the regional differences within one season. Thus the inhomogeneous variations are much more pronounced than the homogeneous. With respect to the seasonal cycle, we can explain 70\% of the \( SLP \) changes by the changes in \( T_{tropos} \) (Fig. 3), which is only 6\% less than in the statistical regression.

Second, it is assumed that the \( T_{tropos} \) changes are given and independent of \( SLP \) changes. Thus \( SLP \) changes are assumed to be a response to \( T_{tropos} \), but do not cause changes in \( T_{tropos} \). This is a simplification, as changes in \( SLP \) or more generally in the atmospheric circulation will cause changes in \( T_{tropos} \). However, the main feature in \( T_{tropos} \) change is the land-sea warming contrast (compare Fig. 1a and 5a top) due to processes and feedbacks that do not involve atmospheric circulation changes (Joshi et al. 2008; Dommenger and Flöter 2011). Indeed the tropical land-sea warming contrast can be reproduced very well in a global energy balance climate model that does not simulate atmospheric circulation changes (Dommenger and Flöter 2011). Thus atmospheric circulation feedbacks can be considered as a secondary effect.
Third, the model does not consider that vertical column extent varies with topography. Since we interpolated all columns to sea level height, we implicitly assumed that this topographic effect is of secondary order.

Fourth, a pressure level exists, in which we have nearly no horizontal gradients in the geopotential height change, so that the mass has to redistribute below this level. This is best valid at the tropopause layer, which is in the tropics roughly at the 100 hPa level (not shown).

5. Projected Trends in the Multi Model Ensemble

Having established the fidelity of our simple model to describe the tropical SLP response to $T_{tropos}$ changes over the seasonal cycle, we can now look at the multi model ensemble mean trends of tropical climate change simulations for the period 1970 to 2099. First we can note that the SLP trend averaged over the entire tropics is 0.05 hPa/100 yrs and is an order of magnitude smaller than the relative trends (about 0.22 hPa/100 yrs; spatial standard deviation of Fig.5a bottom), indicating that mass flow in or out of the tropics is small compared to the tropical internal changes. Thus relative SLP changes in the tropics mark the main signal of tropical SLP changes. In contrast the $T_{tropos}$ absolute trend (3.6°C/100 yrs) is about an order of magnitude larger than the relative trends (up to ±0.4°C/100 yrs).

Figure 5a shows the linear trend patterns in relative $T_{tropos}$ and relative SLP for the period 1970 to 2099. Relative to the tropical mean warming, the troposphere over Africa and South America warms most (Fig. 5a top). A second strong relative warming appears in the very dry trade wind inversions over the eastern parts of the subtropical Atlantic and South Pacific. In agreement with the available moisture dependence of the land-sea warming contrast, the models predict a relative cooling over the Indo-Pacific warm pole region. Thus the strong land-sea contrast of surface and low level warming dominates the $T_{tropos}$ trend pattern. The ensemble mean relative trend of tropical SLP (Fig. 5a bottom) is mostly the opposite to the $T_{tropos}$ trend pattern. This roughly zonal structure shows a mass redistribution from the Atlantic region to the warm pool region, and exhibits, as the $T_{tropos}$ trend pattern, only small seasonal variations (not shown).

Again the strong linear relationship between relative $T_{tropos}$ and relative SLP trends can be illustrated by a scatter plot, see Fig. 5b. The linear regression coefficient between the all $T_{tropos}$ and SLP trend points is -2.0 hPa/K, which is a bit larger in magnitude than the physical model value of -1.7 hPa/K.

In this scatter plot the ocean grid points are colored in blue and the land grid points in red. Most ocean grid points have a negative trend in $T_{tropos}$ and positive trend in SLP, and vice versa for the land grid points. Thus the relatively clear separation of land and ocean grid points in this point cloud illustrates again, that the land-sea warming contrast is the major driver for the tropical SLP changes. However, even if we look at the relation between $T_{tropos}$ and SLP for ocean or land points only we find the same basic linear relationship. The linear regression coefficient and explained variance ($R^2$) values are similar for all ocean points and a bit stronger regression coefficient but smaller $R^2$ value for all land points. This mainly suggests that the link between $T_{tropos}$ and SLP exists also on the smaller scales (e.g. within the continental regions) and is not just between land and ocean contrast, underlining the general relevance of Bjerknes Circulation Theorem in the tropics.

It is important to note here that the relationship of the surface temperature ($T_{surf}$) or SST and the SLP is not as clear as the relationship between $T_{tropos}$ and SLP, because there is some significant changes in the relative warmings at different levels (see Fig.1b). At the near surface (below 850hPa) the direct local or regional land-sea warming con-
tropospheric contrast is dominating, but at the mid levels from 850hPa-400hPa we see the large-scale
hemispheric contrast dominating (see Fig.1b). In total the large-scale hemispheric
warming contrast between the land hemisphere (South America to Africa) and the ocean
hemisphere (Indo-Pacific) is dominating the $T_{tropos}$ trends and thus the SLP trends.

To illustrate the importance of considering the whole tropospheric warming in- stead of just the surface warming, we analyze the relation between $T_{surf}$ or SST and SLP. In Fig. 6 the regression of $T_{surf}$ (black line) and SST (blue line) shows a much weaker re-gression coefficient of 0.3 hPa/K, which can be explained by the stronger gradients at the
surface than in $T_{tropos}$. But more important in the comparison is that with $R^2 = 0.82$
$T_{tropos}$ can explain twice as much of the SLP trends as $T_{surf}$ with $R^2 = 0.40$ and nearly five
as much as SST with $R^2 = 0.17$ in a linear fit. This figure in comparison with Fig. 5b con-
firms as stated in Flohn (1975) that tropospheric temperature can describe the SLP re-
sponse in a warming climate considerably better than (sea) surface temperature.

With the $T_{tropos}$ trends our physical model can explain with 80% only 2% less of the
SLP trends as the statistical regression. The residual SLP trends of the physical mod-
el are shown in Fig. 5c (note the different colorbar): Much of the trend signal is gone, highlighting that the model can explain a large part of the SLP trends, and the residuum
trend shows no longer the large scale mass redistribution but more local trends.

The contrary relationship between relative $T_{tropos}$ and SLP trends can be seen also very nicely in the meridional mean of the two trend pattern (Fig. 5d), with a correlation of -0.94 between the red and the blue curve. The dependency of the responses to the
land warming shows up in comparison with the meridional mean of the tropical land fraction (black line in Fig. 5d), which is smoothed with a running mean of 60° and the
mean value subtracted (correlation of 0.90 with $T_{tropos}$ and -0.84 with SLP) or in compari-
son with the unsmoothed tropical land fraction (gray shaded area in Fig. 5d, correlation
of 0.75 with $T_{tropos}$ and -0.58 with SLP), only disagreeing slightly over the warm pool re-
gion. But this can be explained by the small size of the islands of the Maritime Continent, which will not allow a strong land-sea contrast due to the missing dry inland regions and the close proximity of the oceans for all land points in coarse resolution models.

6. Projected Trends in the Individual CMIP3 Models

The response of individual IPCC models in the A1B scenario can be quite different from model to model. It is therefore instructive to discuss the distribution in the rela-
tionship between the relative $T_{tropos}$ and SLP trends for all the IPCC models. Table 1 lists some important values for all the individual IPCC models. The absolute trends of tropical
$T_{tropos}$ have with values between 2.2 and 5.5°C/100 yrs, on average 3.6°C/100 yrs, nearly
the same spread and magnitude as the trends of the global mean surface temperature
(Meehl et al. 2007a).

Notable are the global mean SLP trends in the models, which suggest some un-
physical trends that will have no impact on the atmospheric circulation. For most mod-
els the trends of the tropical SLP is very similar to the global mean trends (correlation of Tab. 1 column 4 with column 5 = 0.96, root mean square error = 0.85 hPa) indicating
that the trends of air flow in or out of the tropics is much smaller than the tropical mean
SLP trends would suggest. But with an average of 0.05 hPa/100 yrs the multi model
mean has nearly no change for the absolute tropical SLP. These area mean trends of the
tropics are removed to get the relative trend pattern. The spatial standard deviation of
the relative trend pattern varies between 0.07 and 0.23°C/100 yrs, with an average of
0.14°C/100 yrs for $T_{tropos}$ and between 0.20 and 0.78 hPa/100 yrs, with an average of
0.37 hPa/100 yrs for SLP.
The spatial distribution of nearly all IPCC models shows the same characteristic land-sea contrast pattern in the relative \( T_{\text{tropos}} \) and SLP trends (for some models they are shown in Fig. 8). The question arises, if the strength of the land-sea contrast in SLP trends in the individual model depends on the strength of land-sea contrast in \( T_{\text{tropos}} \) trends. In Figure 7 the land-sea contrasts in \( T_{\text{tropos}} \) and SLP are compared against each other. For \( T_{\text{tropos}} \) the land-sea contrast is defined as the ratio between the absolute land and ocean mean warming trend (as defined in Sutton et al. 2007 for surface temperature). We can first of all note that the land-sea contrast of \( T_{\text{tropos}} \) is an order of magnitude smaller than the land-sea contrast of \( T_{\text{surf}} \) (in e.g. Sutton et al. 2007), which is due to much stronger horizontal diffusion in the free atmosphere. For the land-sea contrast in SLP trends we need a different definition, because the definition as ratio between land and ocean SLP trend would not fit here since the absolute trends are positive and negative. We therefore define the land-sea contrast for SLP trends on the basis of the difference between the average ocean and land trends, with ocean weighted with 80% and land with 20% according to their relative fractions in the tropics. Thus large deviations from zero indicate a strong land-sea contrast, as spatially independent distributed trends would yield a value of zero. In this figure we can see, that the models with a strong land-sea contrast in \( T_{\text{tropos}} \) tend to have also a strong land-sea contrast in SLP, which is also indicated by the regression line in black, which shows with a \( R^2 = 0.66 \) a significant relation.

We can take a closer look at the \( T_{\text{tropos}} \) and SLP trends in some models to get an idea to what extent the relationship between \( T_{\text{tropos}} \) and SLP varies. Fig. 8 shows the relative trend pattern and regressions of four models, which cover a wide range of different relationships between \( T_{\text{tropos}} \) and SLP trends.

The BCCR-BCM2.0 model has the weakest land-sea contrast in \( T_{\text{tropos}} \) and a weak sea-land contrast in SLP (see Fig. 7, red square), which can be also seen in the trend pattern in Fig. 8a: The strongest warming takes place over the Pacific Ocean and the Atlantic Ocean and the SLP trends are mostly the opposite (pattern correlation = -0.74). Thus, despite the weak land-sea contrast in \( T_{\text{tropos}} \) the linear relation between \( T_{\text{tropos}} \) and SLP is still strong (Fig. 8b, \( R^2 = 0.55 \)). The regression of ocean only (blue line) and land only (red line) grid points yields similar regression coefficients but a higher \( R^2 \) value for ocean only and a lower for land only. Further the land-sea contrast at surface is with 1.35 in the normal range (not shown) but the land-sea contrast in \( T_{\text{tropos}} \) is with 1.01 (Fig.7) very low, indicating that the coupling between surface and troposphere is different than in the other models.

The MPI-ECHAM5 model has nearly no land-sea contrast in SLP and is in the lower middle of the land-sea contrast range (see Fig. 7, blue diamond), but in the \( T_{\text{tropos}} \) and SLP trend patterns in Fig. 8c the land-sea contrast is clearly imposed on both trend patterns. The SLP trends disagree strongly with our hypothesis above the mountainous regions. The regression (Fig. 8d) shows a relation between these two patterns (\( R^2 = 0.42 \)) and the ocean and land grid points are mostly separated, but not directly along the regression line. The regression for the ocean only and land only grid points has a similar regression coefficient, but a higher \( R^2 \) value for ocean only and an even weaker for land only. Here the land-sea contrast values of \( T_{\text{surf}} \) and \( T_{\text{tropos}} \) are both in the normal range, but the land-sea contrast in SLP is very low (Fig. 7), so that in this model the coupling of \( T_{\text{tropos}} \) and SLP over the mountainous regions, seems to be different from the other models.

The GFDL-CM2.1 model is in the upper middle of the land-sea contrast range (see Fig. 7, green circle) and the trend pattern (Fig. 8e) looks quite similar to those of the Multi Model Ensemble. The land and ocean points are well separated along the regres-
sion line, which show with a $R^2 = 0.72$ a strong relation (Fig. 8f). The regression for ocean only and land only is here quite similar to the all grid points regression.

The UKMO-HadCM3 is the model with the strongest land-sea contrast (see Fig. 7, blue left directed triangle) and in the trend patterns (Fig. 8g) the land-sea contrast is imposed on both trend pattern and the amplitudes are stronger than in the multi model ensemble. The regression (Fig. 8h) shows a clear relation between these two patterns ($R^2 = 0.92$) and a clear separation of ocean and land grid points due to the strong land-sea contrast. Here again the regression for ocean only and land only is quite similar to the all grid points regression. In these four models the $R^2$ value is higher over ocean than over land, with bigger differences in the models where we have only a weak land sea contrast in $T_{tropos}$ or $SLP$, so that the interaction over land seems to be the critical point in these models.

Most of the remaining models have trend pattern that are quite similar to the ones of the Multi Model ensemble. With pattern correlations between the two trend pattern between -0.28 and -0.96, with an average of -0.80 (Tab. 1), we can see that in most of the IPCC models the $SLP$ trends are strongly related to the $T_{tropos}$ trends. The statistical regression of the trend patterns yields values between -1.4 and -2.6 hPa/K (Fig. 9), with an average of -2.1 hPa/K, and $R^2$ values between 0.08 and 0.92, with an average of 0.67. These regression coefficients are on average again a bit stronger than in the simple physical model (black dashed line), indicating that the simple model underestimates the link between $T_{tropos}$ and $SLP$. The simple model can explain in the individual IPCC models between 8% and 84% of the $SLP$ trends, with an average of 63%, but all except one model explaining more than 40% (Fig. 9).

We conclude that the strong coupling between the $T_{tropos}$ and $SLP$ trends is evident in most of the models, even if the land-sea contrast is not the dominant signal in the trends, as in BCCR-CM2.0 model. And models that have a strong land-sea contrast in $T_{tropos}$ trends tend to have also a strong land-sea contrast in $SLP$ trends. Further in most of the models the land-sea contrast is the dominant signal in the trend pattern: As already stated in the introduction the land-sea contrast depends on available moisture, so that we expect a stronger warming in $T_{tropos}$ and decreasing $SLP$ over the South American/African sector and a relative cooling in $T_{tropos}$ and increasing $SLP$ over the Indo-Pacific warm pool region. This is true for nearly all individual models with a strong linear relation (Fig. 10).

### 7. $SLP$ response in idealized $T_{land} +1$ K experiment

We can use a set of atmospheric general circulation model (AGCM) experiments to investigate how the atmospheric circulation responses to tropical land warming. This should give some support for the hypothesis that the $SLP$ trends are being primarily a response to the tropospheric temperature warming pattern, which is dominated by the surface land-sea warming contrast. We therefore analyze some experiments of Dommenget (2009), in which the response of an AGCM to warming of the global land by +1K and cooling of the global land by -1K is simulated. The $SST$ in the AGCM is free to respond, as the $SST$ is simulated by a simple single column ocean mixed layer model; see Dommenget (2009) for details. Thus these experiments are not constructed in a way that they can exactly reproduce the IPCC runs, as the surface land warming is here prescribed homogeneously over all land points, independent from available moisture or distant to the coasts.

The results are shown in Fig. 11, with the response defined as the difference between the land +1K minus the land -1K divided by 2. The ocean warms much less than
1K in response to the 1K surface land temperature increase (Fig. 11a), as discussed in Domménget (2009), and surface temperature has a very strong land-sea contrast of 5.1. The relative response of tropospheric temperature is positive over the continents and mostly negative over the oceans, with higher response over the dry subtropics than over the wetter tropics (Fig. 11c top), as expected from the land-sea warming contrast. In agreement with the Bjerknes Circulation Theorem the SLP response is mostly the opposite of the \( T_{\text{tropos}} \) response (Fig. 11c bottom, pattern correlation -0.89). These patterns have similar trends as the global warming runs over Africa, the Atlantic, South America and the Pacific, but disagree in sign over Southeast Asia, the Maritime Continent and Australia. In the idealised runs we have a clear land-sea contrast signal over the warm pool region, as they are prescribed, but in the IPCC runs there is no land-sea contrast in \( T_{\text{tropos}} \) and SLP. As stated above this difference can be explained with the experimental setup of the idealised experiments, where the land-sea contrast is forced by the fixed land surface temperature change.

A regression between these two response patterns yields a regression coefficient similar to the sensitivity coefficient of the physical model (2.0 hPa/K, Fig. 11b) and 79\% of the SLP response can be explained by the \( T_{\text{tropos}} \) response in a linear fit (77\% in the physical model). The ocean and land grid points are clearly separated along the regression line, indicating that the land-sea contrast is the major forcing in this two trend pattern. In summary, in these idealized experiments the trend patterns support our hypothesis, that land-sea contrast is the major driver for the large scale SLP response in a warming climate.

8. Observed Trends in ERA Interim Reanalysis

We can now look at observed trends in the tropics over the last two decades to see if a strong relation between relative \( T_{\text{tropos}} \) and SLP trends exists there too. However, we have to keep in mind a few important differences between the observed and simulated trends: first, the observed trends are more uncertain than those of the IPCC scenario simulations, due to the much shorter observed time period of 22 yrs versus the 130 yrs of the IPCC scenario simulations used to estimate the trends. Second, it has to be noted that the trends in the 20\(^\text{th}\) century are weaker than those of the 21\(^\text{st}\) century, which will lead to a weaker trend signal in the observation compared to the IPCC scenario simulations. Third is has to be noted that tropical natural variability, such as El Nino, has a stronger impact on relative short time period trends, which will decrease the signal to noise ratio in the observations. Last we have to consider that the observations are just one realization of the warming trend, whereas the IPCC scenario simulations are 23 realizations averaged to one ensemble mean. Thus the observed trends will be much more uncertain and will contain a much larger fraction of internal natural variability than the IPCC scenario simulations.

The trend patterns for the period 1989 to 2010 shown in Fig. 12a have some similarities with the projected trend pattern of the IPCC models, but the amplitudes over ocean are larger than those over land. The overall \( T_{\text{tropos}} \) warming trend of 1.7°C/100 yrs lies within the range of trends due to natural variability simulated by a control simulation of a coupled ECHAM5 model (Bengtsson and Hodges 2009). Again these two patterns are highly anti-correlated (-0.85) and pattern regression yields a regression coefficient of -2.3 hPa/K (Fig. 12b). In the point clouds the land and ocean grid points are only weakly separated, indicating that land-sea contrast is not dominating this trend pattern. The regression for ocean only (blue line) and land only (red line) yields similar values as for all grid points, with a slightly smaller regression coefficient and \( R^2 \) value for land only. The large-scale residuum pattern obtained from the simple model (Fig. 12c) has a
quite similar structure as the trend pattern, but weaker amplitudes. The physical model can explain 68% of the SLP trends.

9. Summary and Discussion

In the study presented above we address the causes of the large-scale tropical SLP changes during climate change. Since tropical SLP is an important indicator for the mean state and variability of the tropical atmospheric circulation we implicitly assume that the analysis of the tropical SLP changes will provide us a basis for understanding changes in the tropical atmospheric circulation. The analysis we present was based on the CMIP3 climate model simulations for future climate change scenarios, the observed seasonal cycle and on recent observations of trends in the tropical climate.

In summary we found a quite robust and strong relationship between the large-scale trends in tropical $T_{tropos}$ and SLP. This relationship is physically based on the thermodynamic response of the SLP to inhomogeneous $T_{tropos}$ warming. In this picture, the trends in the $T_{tropos}$ warming drive the large-scale changes in SLP. This is evident in nearly all IPCC models, independent if land-sea contrast is dominating the two trend pattern or not. With the help of a simple physical model we can measure the ratio between the SLP and $T_{tropos}$ trends (-1.7 hPa/K) and can predict a large part of the SLP trends if we know the $T_{tropos}$ trends. Further the dominating feature of the inhomogeneous $T_{tropos}$ warming, which is in most of the IPCC simulations the land-sea contrast, is imprinted onto the SLP trend pattern as well. This leads to decreased SLP over South America, the Atlantic and parts of Africa and increased SLP over the tropical Indo-Pacific warm pool and implies changes in the regional distribution of tropical deep convection. Indeed all of the IPCC models except one predict increasing SLP and a weaker warming of $T_{tropos}$ over the warm pool region and decreasing SLP and a stronger warming of $T_{tropos}$ over the South American/African region (Fig. 10).

In the comparison of the IPCC models it becomes evident that the models that have a strong land-sea contrast in $T_{tropos}$ tend to have also a strong land-sea contrast in SLP. Further we could support our hypothesis with an idealised sensitivity experiment, in which we prescribed the land warming.

In recent years the tropical SLP response in global warming was often discussed in context of the enhanced hydrological cycle and the accompanied weakening of the tropical circulations, as in Vecchi and Soden (2007, hereafter VS07). This discussion, however, did not consider the second important change of tropical temperature: the land-sea warming contrast. The question arises: How does our new idea fit in their discussion about the weakening Walker Circulation: Their Fig. 10 (top) is similar to our Fig. 5a (bottom) with a similar tendency in the relative SLP trends over the Indo-Pacific warm pool region and the tropical Pacific, even though they only considered SLP changes only over the oceans. VS07 based their argument on the interaction between SST in this region and the Walker Circulation, but found a disagreement between the SLP and SST change. Further, it needs to be noted that our simple model does not make any statement on how the tropical Pacific SST may change, which is central to the VS07 study. The simple model discussed here explains a large fraction of the total SLP trends over the Indo-Pacific warm pool region ($R^2 = 0.81$), but the residuum of this model shows still a decrease in SLP gradient over the Pacific Ocean that would fit to the VS07 study. In turn, our explanation for the roughly zonal SLP response due to inhomogeneous $T_{tropos}$ warming could be the missing piece, why the zonal Walker Circulation weakens stronger than the meridional Hadley Circulation: Two of the three main convection regions (South America and Africa) warm stronger than the third (the Indo-Pacific warm pool), which decreases the relative importance of the latter. This zonal inhomogeneous
distribution of the land-sea contrast leads to zonal changes that affect the Walker circu-
lation, but do not affect the Hadley circulation that much. Thus it seems that both ap-
proaches fit together: VS07 considering the changes in the vertical temperature profile
and this study here the horizontal. However, the results presented in here suggest that
land-sea warming contrast is probably the most important driver of the large scale SLP
change and that future changes in the spatial distribution of relative low SLP, with asso-
associated upward air motion, which would favor deep convection conditions, are strongly
controlled by the changes in near surface relative temperatures.

From reanalysis data the question arises, if the trend in the tropical SLP is the
warming climate signal as seen in the IPCC simulations or if it is natural variability. The
trend patterns show some similarities to those in the IPCC simulations, but this trend
lies within the range of natural variability, simulated by a control simulation of a cou-
pled ECHAM5 model (Bengtsson and Hodges 2009) and both variables have stronger
trends over oceans than over land. Further the negative SLP trend over the Maritime
Continent together with the positive trend over the east Pacific shows an increase in the
zonal SLP gradient over the Pacific, which can be interpreted as an increase in strength
of the Walker Circulation due to natural variability, as proposed by Meng et al. (2011).
The response of equatorial Pacific in a warming climate is a topic of recent research (e.g.
DiNezio et al. 2009; Park et al. 2009) but still model dependent (Latif and Keenlyside,
2009). From these uncertainties in the dynamical response and the short records of ob-
servations it is difficult to assess, what part of observed trends is natural variability and
what is climate change. However, the relative trends of $T_{trop}$ and SLP in observations
are also strongly related, following mostly the simple thermodynamical model discussed
in this study.

## Acknowledgments

We acknowledge the individual modeling groups, the Climate Model Intercomparison
Project (CMIP3) and ECMWF for providing the data sets. This work was supported by
the Deutsche Forschungsgemeinschaft (DFG) through project DO1038/5-1. We thank
